Abstract. Kariological investigation of the earthworm *Octodrilus transpadanus* (Rosa, 1884) in the Ukraine showed that this species is represented by at least three races of different ploidy with the basic chromosome number $n=15$. Strict geographic heterogeneity of electrophoretic spectra of different populations was registered: south-eastern populations ($7n=105$) are characterized by a clonal structure, whereas western (from $3n = 45$ to $4n = 60$) and south-western ($2n=30$) ones have a high level of polymorphism. The Crimea sample ($4n=60$) is well isolated, has no clonal structure and is characterized by a series of specific alleles, which are absent in forms from continental Ukraine. All the forms turned out to be well isolated morphologically, except for the clonal forms, which are very much alike.

Key words: earthworms, *Octolasion*, *Octodrilus*, polyploidy, genetic structure, morphology.

INTRODUCTION

The Mediterranean species *Octodrilus transpadanus* (Rosa, 1884) is widely distributed in the east and the south of the Ukraine (Zrazhevsky, 1957; Perel, 1979; Buslenko, 2005). It is a moisture-loving species which lives deep in the soil and prefers grey forest soils, meadow-steppe and common black soils.

At present there are different views on the genus affiliation of this species. For a long time it was ascribed to the genus *Octolasion* Orley, 1885. Later, on the basis of new taxonomic features (the presence of diverticula in the 10-th segment, the quantity of spermathecae and

chromosome numbers) P. Omodeo suggested the division of this genus into two subgenera: *Octolasion (Incolore)* and *Octolasion (Purpureum)* (Omodeo, 1952). Later he renamed *Octolasion (Purpureum)* into *Octodrilus* (Omodeo, 1956). Bouché (1972) promoted subgenus *Octodrilus* to the rank of genus and included in it *Octodrilus transpadanus*. As a result of one of the last revisions of the Lumbricidae (Christian, Zicsi, 1999) one more genus *Octodriloides* Zicsi, 1986, was separated from the genus *Octodrilus*. *O. transpadanus* remained in the latter one.

It is necessary to note that this initiative was not supported by all researchers. T.S.

Vsevolodova-Perel (1997) holds to the broader concept of *Octolasion* genus, combining all species of three mentioned above genera into one genus on the basis of the same form and orientation of the nephridial bladders. According to this point of view *O. transpadanus* belongs to the genus *Octolasion*.

The first karyological investigation of *O. transpadanus* was made in Italy (Omodeo, 1952). It was established that earthworms of this genus are represented in Italy by the diploid race ($n=18$) (Omodeo, 1952) and reproduce by amphimixis. Later the chromosome number was defined more precisely. As it turned out, the haploid set of *O. transpadanus* consists not of 18 but of 15 elements (Omodeo, 1962). Earthworms of this species from other populations had the same haploid chromosome number ($n=15$, $2n=30$) (Bakhtadze, 2008; Omodeo, 1962; Casellato, 1987; Vedovini, 1973). Thus, according to published data, all specimens of *O. transpadanus* were diploid.

At present the genetic structure of populations of many Lumbricid species is rather well investigated (Terhivuo, Saura, 2006; Vlasenko et al., 2007; Mezhdzherin et al., 2008). However, researchers have been interested basically in study of polyploid complexes, which are characterized by the clonal structure of populations. As *O. transpadanus* is considered a classical diploid, populational and genetical studies of this species have not been conducted previously.

In the Ukraine *O. transpadanus* has been found repeatedly (Zrazhevsky, 1957; Perel, 1979), but karyological investigations have not been conducted. The purpose of this work is to describe the karyotypes and perform comparative analysis of chromosome sets of *O. transpadanus* from different parts of the Ukraine.

MATERIAL AND METHODS

The material for this study was collected in the spring-autumn period of 2005-2008 using generally accepted methods (Byzova et al., 1987). 9 samples from the Ukraine have been investigated (Vylkove town, Odessa region; Dnipropetrovsk city; Nastasivka village, Dnipropetrovsk region; Kotelva village, Poltava region; Mostove village, the Crimea; Novostanichnoe village, Lugansk region; Kalnyk village, Kincses village, and Irlava village, Zakarpats'ka region).

79 specimens, identified as *O. transpadanus* according to tables of Perel (1979) and Vsevolodova-Perel (1997), were used for karyological investigations. Preparations for the analysis were made from 32 specimens.

Karyological preparations were made from seminal vesicles with methods previously used in Lumbricidae investigations (Garbar, Onyschuk, 2007; Garbar, Vlasenko, 2007). The earthworms were injected with 0.1% colchicine 19 hours before the dissection.

The spermatocytes were placed for 50 minutes in distilled water and fixed in the 1:3 mixture of glacial acetic acid and ethanol. Chromosome preparations were obtained by the reprint method (Sitnikova et al., 1990). Dried preparations were stained with Romanovsky type stain in 0.01M phosphate buffer (pH 6.8). The preparations were analysed with a «Mikmed» microscope (10x90).

Electrophoretic variability of spectra of enzymes (aspartate aminotransferase (AST), malate dehydrogenase (MDH), nonspecific esterases (ES) and superoxide dismutase (SOD) in extracts from a caudal part of body was investigated by the method of PAG-electrophoresis in Tris-EDTA-borate buffer system (Peacock et al., 1965).

Morphological investigations were conducted on fixed worms. Length of whole body (L), forward end of body (l_1), clitellum (l_2),

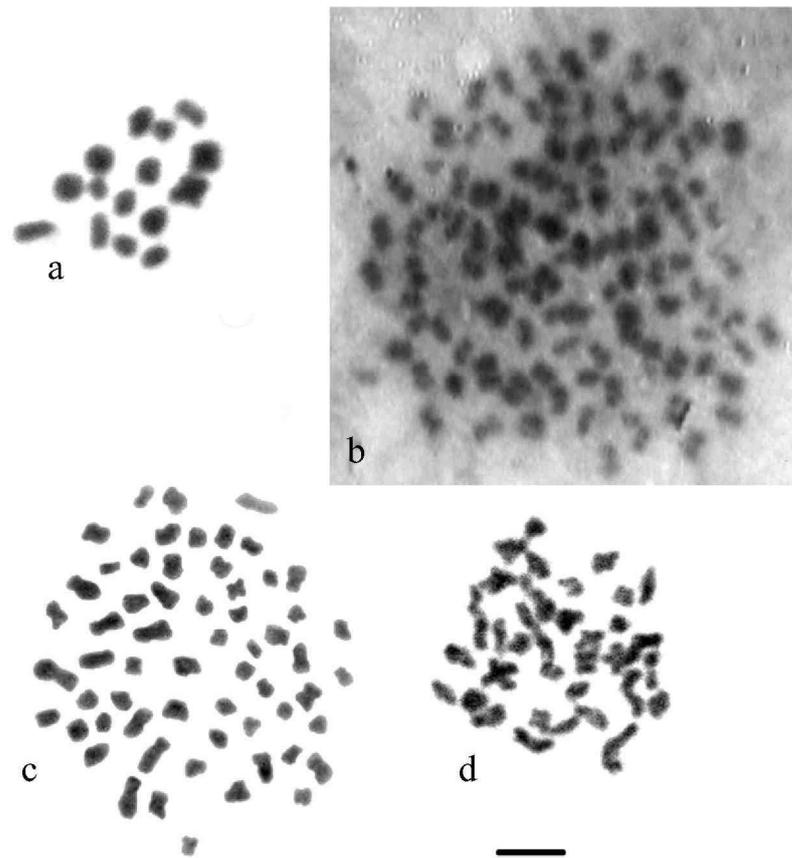

Fig. 1. The chromosomes of *O. transpadanus*. **a** - the diakinesis of diploid specimen from Vylkove ($n=15$). **b** - mitotic metaphase of heptaploid specimen from Dnipropetrovsk ($7n \approx 105$). **c** - mitotic metaphase of tetraploid specimen from Kalnyk ($2n=60$). **d** - diakinesis of tetraploid specimen from Kalnyk. $2n=10 \mu\text{m}$.

and the maximal diameter of a body behind clitellum (d) were measured. Total number of segments (n_1) and number of segments up to clitellum (n_2) were counted. The size and position of the clitellum, the form and position of pubertate platens, the form of the head blade, distance between setae, position of spinal pores and papillae were defined. The average length of one segment (L/n_1) and the average length of one segment up to clitellum (l_1/n_2) were calculated and the number of indices, describing the relative sizes of a body, was counted.

Statistical processing of obtained data was carried out by means of a package of applied

statistical programs STATISTICA 6.0.

RESULTS AND DISCUSSION

Karyological analysis

Vylkove town, Odessa region. All investigated specimens of *O. transpadanus* from this population turned out to be diploid ($2n=30$). At the stage of spermatogonial meiosis 15 bivalents were registered (Table 1 and Fig. 1, a).

Dnipropetrovsk city. The chromosome number of earthworms from this sample was established approximately. The chromosome number in the mitotic metaphase exceeded

100. These specimens probably had 7 fold level of chromosome set ploidy (7n) with the basic chromosome number n=15 (Table 1, Fig. 1, b).

Kalnyk village, Zakarpats'ka region. Worms from this sample have the number of chromosomes in mitotic metaphase that varied from 45 up to 60 (Table 1, Fig. 1, c, 1, d). It is possible that in this population we observe coexisting triploid and tetraploid races.

Mostove village, the Crimea. Specimens of *O. transpadanus* from this collection site turned out to be tetraploid with the basic chromosome number n=15. Their mitotic metaphases had 60 two-armed chromosomes (FN=120) (Fig. 1, c). At the stage of diakinesis in spermatogonial meiosis the number of elements varied but always exceeded the haploid number. In addition to that the plates always

had polyvalents (Table 1, Fig. 2).

The obtained data prove that in the Ukraine *O. transpadanus* is represented by a series of races with different level of ploidy. According to published information it is a diploid amphimictic species in Italy, France, and Georgia (Omodeo, 1962; Casellato, 1972; Vedovini, 1973; Bakhtadze 2008). In the investigated Ukrainian localities we discovered four forms of *O. transpadanus* with different ploidy levels: diploid (2n=30), triploid (3n=45), tetraploid (4n=60) and, perhaps, heptaploid (7n>100). The presence of both unpaired and paired ploidy forms testifies to the hybrid nature of polyploidy in *O. transpadanus*. This view is supported by the character of meiosis in polyploids (variable number of polyvalents, unstable number of elements) (Fig. 1, d).

Numerous changes observed in the meio-

Fig. 2. The chromosomes of tetraploid *O. transpadanus* ($4n=60$) from Mostove village (the Crimea). **a** - mitosis metaphase. **b** - diakinesis. **c** - karyogram. $2n=10\ \mu\text{m}$.

sis in polyploid races probably testify the occurrence of reproduction by apomixis, which is typical for polyploid races of earthworms.

Diploid races with normal spermatogonial meiosis reproduce by amphimixis (Omodeo, 1962; Casellato, 1972; Vedovini, 1973).

Biochemical gene marking

To investigate the genetic structure of *O. transpadanus* populations the variability at four enzyme systems that generate reliable and reproducible results in electrophoresis conditions (Peacock et al., 1965) was studied: aspartate aminotransferase (AST), superoxyde dismutase (SOD), malate dehydrogenase

(MDH) and non-specific esterases (ES), coded with a series of loci. The last two enzymes were variable.

Comparison of the variability of electrophoretic spectra of different populations have shown a distinct geographic heterogeneity: the south-eastern populations have a clonal structure, whereas the western and south-western ones are polymorphic (Table 3 and Fig. 3).

In the first group two main forms differing in MDH spectra were identified. An electromorph, corresponding to conventional MdhB genotype, is fixed in one group and MdhAB heterozygote is presumed to be fixed in the other. Clone specimens of MdhB electropho-

retic type were found in Dnipropetrovsk (6 individuals) and Poltava region (Kotelva village, 3 individuals), also the latter have peculiar alleles in Es-6 locus. Specimens of an alternative clone with MdhAB electrophoretic type were found in Dnipropetrovsk (5 individuals), Dnipropetrovsk region (Nastasivka village, 6 individuals) and Lugansk region (Novostanichnoye village, 2 individuals).

Unlike south-eastern *O. transpadanus* populations, the western and south-western ones are not only more numerous, which is reflected in the higher number of investigated samples, but also characterized by an excep-

tionally high level of genetic polymorphism. The variability of non-specific esterase loci in the population from Odessa region (Vylkovo town, 38 individuals) and Transcarpathian region (Kalnic village, 11 individuals; Kinchesh village, 33 individuals; Irlava village, 41 individuals) was so high that it was virtually impossible to find within a sample two specimens with the identical spectra. Analysis of spectra has shown that there is no clear tendency for equal distribution of homo- and heterozygote genotypes of certain loci, which is characteristic of amphimictic organisms and has been recorded for diploid species of earthworms (Mezhzherin et al., 2008; Stille et al., 1980). The situation resembles the cases of hypervariability in organisms, producing gametes in upset meiosis (Cywinska, Hebert, 2002). As a result, the genetic variability in a population greatly increases and every specimen becomes as unique as if it were a separate clone. A similar case was registered in the parthenogenetic species *Aporrectodea rosea* (Savigny, 1826) with different levels of ploidy, populations of which have either a strict clonal structure (Vlasenko et al., 2007) or are an aggregate of specimens where each individual has its unique spectrum (Vlasenko, 2008).

A peculiar interest is provoked by the *Mdh*

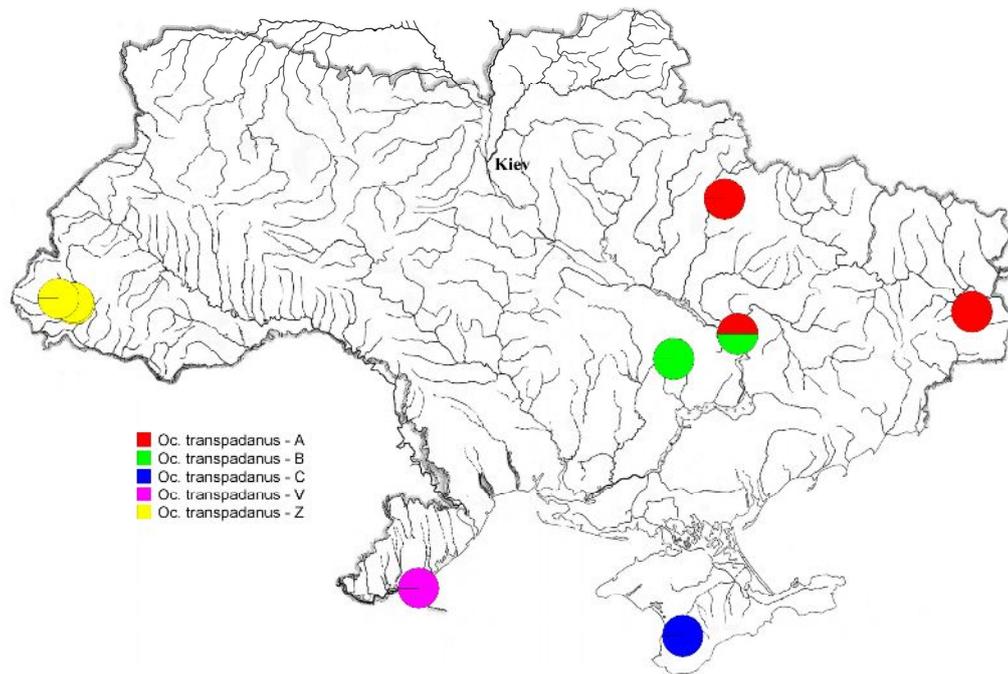

Fig. 3. The distribution of *O. transpadanus* genetic forms in the Ukraine.

locus, which is weakly variable in the Vylkovo population, but is highly polymorphic in the Zakarpats'ka region. The spectra of this locus are characterized by unbalanced combinations of homo- and heterozygotes, and most heterozygotes show the so-called dose effect (Table 2). An attempt to find a correlation between spectra types of MDH and non-specific esterases for separate specimens was not successful and proved the non-clone character of variability in this population.

The sample from the Crimea (Mostove village, 3 individuals) is different from other *O. transpadanus* populations. It is characterized by polymorphism of spectra of both non-specific esterases and MDH so it doesn't have clone structure but is characterized by a series of specific alleles, absent in continental forms. It is evident that in the Crimea there is either an old divergent form or a form gener-

ated with *O. transpadanus* continental forms. From our point of view this is the reason why the Crimean form should be considered as a separate species.

Analysis of morphological peculiarities

Average values of investigated parameters of *O. transpadanus* genetic forms are given in Table 4. All specimens in general corresponded to the species descriptions (Perel, 1979; Christian, Zicsi, 1999) and were reliably identified by diagnostic characteristics. At the same time the analysis of morphological features has shown reliable differences in genetic forms (Table 5).

The earthworms from the Crimea (form (C.)) turned out to be the most isolated by morphology and reliably differed from all other forms by 8-9 out of 12 used features (Table 5). They were also characterized by the high-

est values of all size characteristics (Table 4). Genetically polymorphic populations from the Zakarpats'ka region (form (Z.)) and Vylkovo (form (V.)) reliably differed from one another by 10 characteristics. At the same time form (V.) is very close to both clone forms, A and B, as it reliably differs from them by only one characteristic, whereas form (Z.) reliably differed from forms A and B by 7-8 characteristics (Table 5). Significant differences be-

tween clone forms were not found.

Analysis of a combined sample of all forms (Table 6) has shown that there is the significant morphological isolation of Crimean earthworms (form (C.)) from all other forms: they are discriminated at 100 % level (Table 6). The discrimination level of forms (V.) and (Z.) is rather high - 80 % and 96 % accordingly. It is necessary to mention that representatives of clone forms are not effectively discriminated

but are somewhat isolated from all the others. Cluster analysis of the set of morphological parameters has shown similar results (Fig. 4).

CONCLUSIONS

Karyological investigation of *O. transpadanus* earthworms in the Ukraine has shown that this species is represented by at least three races of different ploidy with the basic chromosome number $n=15$.

Strict geographic heterogeneity of electrophoresis spectra of different populations is registered: south-eastern populations ($7n=105$) are characterized with clone structure, whereas western (from $3n = 45$ to $4n = 60$) and south-western ($2n=30$) ones have high level of polymorphism. The Crimea sample ($4n=60$) is well isolated, has no clonal structure and is characterized by a series of specific alleles, which are absent in forms from continental Ukraine.

All the forms turned out to be well isolated morphologically, except for clonal forms that are very much alike.
